Abstract

This pilot examines how inter-individual differences moderate the effectivity of cyber-manipulation on political opinions using an ontology-driven multi-agent simulation pipeline. Run 6 uses an attacked-only profile-panel design in which one fixed misinformation leaf is applied to each pseudoprofile across multiple political-opinion leaves. Attack effectivity is defined as within-profile post-minus-baseline movement, with absolute shift $A_{ik} = |\text{post}_{ik} - \text{baseline}_{ik}|$ as the primary outcome so that issue-specific signed movements do not cancel out. The pilot generated 50 pseudoprofiles, 200 attacked opinion rows, and 4 repeated attacked outcomes per profile. Mean absolute attacked shift was 41.65, mean signed shift was 22.05, mean attack realism was 0.69, and mean post-exposure plausibility was 0.75. The structural model is now a repeated-outcome path SEM in which multiple attacked opinion deltas are regressed on profile moderators simultaneously. To compute a profile-level susceptibility summary without inheriting multicollinearity from a small-sample OLS, a cross-validated ridge aggregation is fit after the run and converted into a post hoc empirical susceptibility index. The pilot should therefore be read as methodological validation and exploratory evidence rather than as claim-ready causal estimation.

1 Introduction

Political influence campaigns increasingly operate in the space between mass communication, personalized persuasion, and platform-native misinformation. Rather than relying on technical compromise alone, they often work through selective framing, pseudo-consensus, strategic ambiguity, distrust activation, and identity-congruent narrative design (Bennett & Livingston, 2018; Lazer et al., 2018; Lewandowsky et al., 2017; Pennycook & Rand, 2019, 2021; Vosoughi et al., 2018). This makes the key research problem not only whether content is false, but whether the cognitive conditions of judgement are being shaped in ways that weaken self-directed political belief formation.

That concern is closely related to recent discussions of cognitive warfare and cognitive superiority in security policy. NATO-oriented analyses increasingly frame the contested terrain as one in which human attention, interpretation, trust, and decision-making become operationally relevant dimensions of conflict and competition (Johns Hopkins University & Imperial College London, 2021; Hung & Hung, 2022; Paulauskas, 2024). The present study adopts *cognitive sovereignty* as the substantive framing for whether political opinion formation remains self-directed under digital adversarial pressure.

The research question is straightforward: *How do inter-individual differences moderate the effectivity of cyber-manipulation on political opinions?* The methodological challenge is less

straightforward. A real-world dataset that cleanly aligns profile structure, attack-vector semantics, repeated political-opinion items, and post-exposure response states is difficult to obtain, ethically constrained, and often poorly matched to ontology-level modeling. This makes a transparent, auditable simulation architecture useful as a methodological instrument, provided the architecture is explicit enough to be criticized and improved (Cioffi-Revilla, 2002; Rosseel, 2012).

2 Materials and Methods

2.1 Ontology-Constrained Pilot Design

Run 6 uses three hierarchical ontologies: PROFILE, ATTACK, and OPINION. The ontologies remain hierarchical in storage, but estimation is leaf-based. PROFILE combines continuous leaves (e.g., age and Big Five means) with categorical leaves (e.g., sex). ATTACK contributes one fixed pilot leaf, `ATTACK_VECTORS > Social_Media_Misinformation > Misleading_Narrative_Framing`. OPINION contributes repeated leaf nodes from the focused domain Defense_and_National_Security.

The design is attacked-only. Each pseudoprofile is crossed with multiple opinion leaves, so one fixed attack leaf is connected to multiple attacked deltas for the same individual profile. This architecture is more coherent with the moderation question than a treatment-versus-control setup when the research focus is heterogeneity of attack effectivity under exposure rather than incremental exposure effects relative to no exposure.

2.2 Baseline, Exposure, and Post-Exposure Assessment

For each profile i and opinion leaf k, the pipeline elicits a baseline opinion and a post-exposure opinion on a signed integer scale from -1000 to $+1000$. Exposure texts are generated as realistic social-media-native manipulative messages, then audited for realism. Post-exposure responses are audited for coherence and boundedness. This means every analyzed row is not merely a model output, but a generated output that has passed a second review layer designed to detect implausible reversals, coarse rounding, and issue-incoherent response shifts.

2.3 Effectivity Outcome and Profile-Level Susceptibility

The signed attacked shift for profile i on opinion leaf k is

$$\Delta_{ik} = \text{post}_{ik} - \text{baseline}_{ik}, \tag{1}$$

and the primary effectivity outcome is the absolute attacked shift

$$A_{ik} = |\Delta_{ik}|. \tag{2}$$

The profile-level observed effectivity summary is the mean attacked shift magnitude

$$E_i = \frac{1}{K} \sum_{k=1}^{K} A_{ik}, \tag{3}$$

where K is the number of repeated opinion leaves for profile i.

The repeated-outcome SEM is a profile-level path model:

$$A_{ik} = \alpha_k + X_i\beta_k + C_i\gamma_k + \varepsilon_{ik}, \tag{4}$$

where each repeated attacked opinion outcome A_{ik} is regressed on the same profile vector X_i and control vector C_i, while residual covariance between attacked opinion leaves is estimated within the SEM.

The post hoc empirical susceptibility index is not an input variable. It is derived after estimation from the regularized profile aggregation:

$$S_i^* = \mathrm{PctRank}\left(\frac{1}{K}\sum_{k=1}^{K}\sum_{j}\hat{\beta}_{jk}^{(\mathrm{ridge})}X_{ij}\right). \tag{5}$$

This index is therefore descriptive. It summarizes the model-implied profile propensity toward larger attack effectivity after the run has been completed while shrinking unstable coefficient combinations.

3 Results

Run 6 generated 50 pseudoprofiles and 200 attacked opinion rows. The fixed attack leaf was linked to 4 repeated opinion indicators per profile. Mean absolute attacked shift was 41.65 and mean signed shift was 22.05. Mean attack realism was 0.69, while mean post-exposure plausibility was 0.75.

The measurement-and-moderation structure is summarized in Figure 1. Figure 2 shows the distribution of absolute attacked deltas across repeated opinion leaves. Figure 3 shows the descriptive susceptibility weights that summarize the post hoc profile index, and Figure 4 shows the repeated-outcome path-SEM coefficient matrix. The strongest normalized moderator weights in run 6 were Age Years (20.6% of normalized moderator weight); Sex Female (18.0% of normalized moderator weight); Big Five Neuroticism Mean % (14.9% of normalized moderator weight); Sex Other (10.6% of normalized moderator weight). At the ontology-group level, the largest aggregated weight shares were Demographics: Sex (28.6%); Demographics: Age (20.6%); Personality: Neuroticism (14.9%).

Figure 1: Run 6 attacked-only profile-panel design.

Note. One fixed ATTACK leaf is connected to multiple attacked OPINION leaves for each PROFILE. Hierarchical ontologies are preserved upstream, while estimation is leaf-based and repeated within profile.

Figure 2: Absolute attacked opinion shift by repeated opinion leaf.

Note. Absolute shift is the primary effectivity outcome because a single attack leaf can generate signed movement in different directions across different opinion leaves.

Figure 3: Descriptive susceptibility weights across profile moderators.

Note. Bars show the normalized contribution of each profile moderator to the post hoc susceptibility index after ridge regularization across the repeated attacked opinion outcomes.

Figure 4: Repeated-outcome path-SEM coefficients across attacked opinion leaves.

Note. Cells show SEM path coefficients from profile moderators to attacked opinion-shift indicators. The fixed ATTACK leaf is constant by design and therefore represented in the study design rather than as a varying regressor.

The repeated-outcome path SEM converged with CFI = 1.000 and RMSEA = 0.000. Those fit indices should still be read cautiously because the model is relatively dense for a pilot of this size and several paths are being screened simultaneously. The clearest leaf-specific paths were Sex Female -> Defense Spending Increase Support (b = -12.73, p = 0.018); Big Five Neuroticism Mean % -> Conscription Support (b = 5.73, p = 0.031); Sex Female -> Conscription Support (b = 13.59, p = 0.053); Big Five Neuroticism Mean % -> Alliance Commitment Support (b =

Sex Female	core	3.246	0.188	1.521	17.954	1.052	7.857	0.018	4.000
Age Years	core	2.592	0.073	1.454	20.561	3.036	3.036	0.132	4.000
Big Five Conscientiousness Mean %	core	0.396	0.755	0.053	9.536	0.590	2.086	0.108	4.000
Big Five Neuroticism Mean %	core	1.039	0.382	0.931	14.924	0.825	2.635	0.031	4.000
Big Five Openness To Experience Mean %	core	-0.916	0.418	0.042	4.004	-0.458	1.174	0.168	4.000
Big Five Agreeableness Mean %	exploratory	1.369	0.211	0.300	4.059				
Big Five Extraversion Mean %	exploratory	-1.151	0.425	0.357	8.642				
Resilience Index	exploratory	-0.419	0.757	-0.330	9.711				

Note. Controlled coefficients summarize moderator associations with mean attacked effectivity. SEM columns summarize the repeated-outcome path model across the attacked opinion leaves. Weight percentages come from the regularized profile aggregation used to compute the post hoc susceptibility index.

-3.45, p = 0.105); Big Five Conscientiousness Mean % -> Alliance Commitment Support (b = 3.67, p = 0.108); Age Years -> Defense Spending Increase Support (b = 4.05, p = 0.132). These p-values are unadjusted and should be interpreted as exploratory. The post hoc susceptibility ranking identified the highest-scoring profiles as profile_0012 (100.0th percentile; mean $|\Delta|$ = 54.2); profile_0105 (98.0th percentile; mean $|\Delta|$ = 46.8); profile_0215 (96.0th percentile; mean $|\Delta|$ = 54.5). The Spearman alignment between the post hoc susceptibility ranking and the observed effectivity percentile was 0.412, which is useful descriptively but should not be over-interpreted as external validation. Controlled summary contrasts and ridge-derived weights together suggested that the most influential profile components in this pilot were Age Years (controlled b = 2.59, p = 0.073, weight = 20.6%); Sex Female (controlled b = 3.25, p = 0.188, weight = 18.0%); Big Five Neuroticism Mean % (controlled b = 1.04, p = 0.382, weight = 14.9%); Sex Other (controlled b = -2.92, p = 0.263, weight = 10.6%); Resilience Index (controlled b = -0.42, p = 0.757, weight = 9.7%).

4 Discussion

Run 6 improves the methodological coherence of the study in three ways. First, the design now directly answers the moderation question under attack rather than drifting into a treatment-versus-control estimand. Second, effectivity is treated as a repeated construct: the same attack leaf is linked to multiple attacked opinion outcomes per profile, and those outcomes remain visible in the SEM instead of being collapsed prematurely. Third, the personal susceptibility index is no longer injected a priori as if it were observed truth. Instead, it is computed post hoc from a regularized aggregation of fitted moderator weights and can therefore be interpreted as a model-derived profile summary.

These changes matter because the research question is not simply whether misinformation can move opinions. The more specific question is which inter-individual differences are associated with larger movement once exposure occurs. In that sense, the attacked-only repeated-leaf design is a cleaner pilot architecture for studying heterogeneity of cyber-manipulation effectivity. The fixed attack leaf reduces attack-side heterogeneity, the repeated opinion leaves reduce item idiosyncrasy, and the moderator-weight table makes the final susceptibility ranking decomposable rather than opaque.

The pilot still has clear limits. The agents are synthetic. The exposure remains one fixed attack leaf. The sample, while larger than earlier pilots, is still modest for high-confidence inference. The path-SEM fit is encouraging but should not be mistaken for definitive construct validation in a near-saturated pilot setting. The post hoc susceptibility index is descriptive because it is derived from fitted model weights rather than observed externally. The current results therefore validate the research workflow more than they establish external truth about real populations.

5 Conclusion

This pilot demonstrates that an ontology-driven multi-agent simulation can be structured to study heterogeneity in cyber-manipulation effectivity with substantially better methodological alignment than the earlier pilots. The core move is to treat one fixed attack leaf as producing multiple attacked opinion-shift indicators per profile, estimate those repeated outcomes jointly, and derive the final susceptibility index only after the full profile moderation structure has been

estimated. Run 6 is therefore a stronger methodological answer to the stated research question, even though it remains exploratory and should be scaled further before substantive claims are made.

A Supplementary Materials

Figure 5: Baseline versus post-attack opinion scores.

Note. The diagonal marks no change. Points are colored by opinion leaf so issue-specific movement remains visible without collapsing the political state space to a single item.

Figure 6: Per-profile attack effectivity heatmap.

Note. Profiles are ordered by the post hoc empirical susceptibility index. Cells show mean absolute attacked shift for each repeated opinion leaf.

Figure 7: Distribution of the post hoc empirical susceptibility index.

Note. The susceptibility index is the percentile-ranked profile-only linear predictor from the ridge-regularized aggregation of repeated attacked opinion outcomes. It is descriptive rather than independent evidence.

Table 4: Ontology leaves used in the run_6 pilot.

Ontology	Role	Leaf
ATTACK	Fixed pilot leaf	ATTACK_VECTORS > Social_Media_Misinformation > Misleading_Narrative_Framing
OPINION	Repeated indicator leaf	Issue_Position_Taxonomy > Defense_and_National_Security > Alliance_Commitment_Support
OPINION	Repeated indicator leaf	Issue_Position_Taxonomy > Defense_and_National_Security > Conscription_Support
OPINION	Repeated indicator leaf	Issue_Position_Taxonomy > Defense_and_National_Security > Defense_Spending_Increase_Support
OPINION	Repeated indicator leaf	Issue_Position_Taxonomy > Defense_and_National_Security > Strategic_Autonomy_Support

Note. Only ontology leaves are sampled for estimation. The ATTACK ontology contributes one fixed pilot leaf; the OPINION ontology contributes repeated indicator leaves.

Table 5: Core and exploratory profile moderator comparison.

Moderator	Role	Multivariate b	Multivariate p	Univariate b	Univariate p	Ontology group	Normalized weight %
